

A SURGICAL RETRACTOR PLATFORM BLADE APPARATUSFIELD OF THE INVENTION

The present invention relates generally to surgical instruments, and more particularly to surgical retractor, instrument mount, and tissue stabilizer devices for use during coronary artery bypass graft surgery.

BACKGROUND OF THE INVENTION

Diseases of the cardiovascular system affect millions of people each year and are a leading cause of death throughout the world. The cost to society from such diseases is enormous both in terms of the number of lives lost as well as in terms of the costs associated with treating patients through traditional surgical techniques. A particularly prevalent form of cardiovascular disease is a reduction in the blood supply leading to the heart caused by atherosclerosis or other condition that creates a restriction in blood flow at a critical point in the cardiovascular system that supplies blood to the heart.

Treatment of such a blockage or restriction in the blood flow leading to the heart is, in many cases, treated by a surgical procedure known as a coronary artery bypass graft (CABG) procedure, more commonly known as a "heart bypass" operation. In the CABG procedure, the surgeon "bypasses" the obstruction to restore normal blood flow to the heart either by attaching an available source vessel to the obstructed target coronary artery or by removing a portion of a vein or artery from another part of the body, to use as a graft, and installing the graft between a point on a source vessel and a point on a target artery.

To restore the flow of blood to the heart, the CABG procedure requires that a fluid connection be established between two vessels. This procedure is known as an "anastomosis." Typically, a source vessel, such as a source artery with an unobstructed blood flow, i.e., the left internal mammary artery (LIMA), or a bypass-graft having one end sewn to an unobstructed blood source such as the aorta, is sewn to a target occluded coronary artery, such as the left anterior descending (LAD) artery or other vessel, that provides blood flow to the muscles of the heart.

Although the CABG procedure has become relatively common, the procedure itself is lengthy and traumatic and can damage the heart, the cardiovascular system, the central nervous system, and the blood supply itself. In a conventional CABG procedure, the surgeon makes an incision down the center of the chest, cuts through the sternum, performs several other procedures necessary to attach the patient to a heart-lung bypass machine, cuts off the blood flow to the heart, and then stops the heart from beating in order to complete the bypass. The most lengthy and traumatic surgical procedures are necessary, in part, to connect the patient to a cardiopulmonary bypass (CPB) machine to continue the circulation of oxygenated blood to the rest of the body while the bypass is completed.

In recent years, a growing number of surgeons have begun performing CABG procedures using surgical techniques especially developed so that the CABG procedure could be performed while the heart is still beating. In such procedures, there is no need for any form of cardiopulmonary bypass, no need to perform the extensive surgical procedures necessary to connect the patient to a cardiopulmonary bypass machine, and no need to stop the heart. As a result, these beating heart procedures are much less invasive

and the entire procedure can typically be achieved through a small number, typically one or two, comparatively small incisions in the chest.

Despite the advantages, the beating-heart CABG procedure is not universally practiced, at least in part, because of the difficulty in performing the necessary surgical procedures using conventional surgical instruments. For example, it has been difficult for the surgeon to access the required areas of the heart requiring revascularization. In addition, the various surgical steps that are required to be performed on the heart itself are more difficult to perform because the heart muscle continues to move and contract to pump blood throughout the duration of the procedure.

The specific portion of the surgical procedure that creates the anastomosis in the beating-heart CABG procedure is particularly difficult. Completion of the anastomosis requires placing a series of sutures through extremely small vessels on the surface of the heart while the heart muscle continues to beat. Moreover, the sutures must be carefully placed to ensure that the source vessel or graft is firmly attached and will not leak when blood flow through the vessel is established. In cases where the target coronary artery is temporarily obstructed, for example, to improve the surgeon's visibility and avoid excessive blood loss, it is also important that the anastomosis procedure be performed rapidly to avoid ischemic damage to the heart.

Further adding to the difficulty of the procedure is the fact that the working space and visual access are often quite limited. The surgeon may be working through a small incision in the chest, for example, or may be viewing the procedure on a video monitor if the site of the surgery is viewed via surgical scope. The vessel, and particularly the

arteriotomy to which a source vessel is to be anastomosed, may also be very difficult for the surgeon to see as it may be obscured more or less by layers of fat or other tissue.

The beating-heart CABG procedure could be greatly improved if the heart could be accessed and stabilized during the procedure such that the motion of the heart, particularly at the site of the anastomosis, is minimized even though the heart continues to beat and supply blood to the body. The beating-heart CABG procedure could be further improved if the target vessel, and specifically the arteriotomy was presented to the surgeon in a way that allows sutures to be easily placed.

In view of the foregoing, it would be desirable to have improved devices for accessing and effectively stabilizing the beating heart at the site of the anastomosis. It would be desirable to have a retractor system that provides unobstructed and organized access to the areas of the heart requiring revascularization. It would be further desirable to have a low-profile, atraumatic stabilizing device that stabilizes the beating heart at the site of the anastomosis and provides a favorable presentation of the target vessel and the arteriotomy. It would be further desirable to provide a mount for the stabilizing device, or other instruments, that allows the stabilizing device to be easily maneuvered to the desired position and orientation, fixedly secured until the procedure is completed, and then easily removed from the site of the anastomosis.

SUMMARY OF THE INVENTION

The present invention will be described for use in performing CABG surgery, but the invention is not limited thereto, and is contemplated to be useful for other surgical procedures requiring access through an incision into a patient.

The present invention involves various aspects of a surgical retractor for use, for example, in performing a CABG procedure on a beating heart. The present invention may involve a surgical retractor platform blade which facilitates the creation of a working opening through an incision in a patient, such as a sternotomy, and may also provide a platform for securely mounting various instruments or for organizing such things as sutures. The present invention may also include an instrument mount which may be secured to the platform.

One aspect of the present invention involves a surgical retractor blade for attaching to a drive mechanism for use in spreading apart opposite sides of an access incision in a patient. The retractor blade may have a unitary body which includes a first end, a second end, and a channel adapted to engage one side of an incision in patient, preferably an incised sternum. The body is preferably polymeric, but may be metal, a composite material, or other suitable substantially rigid, load bearing material. The first end preferably has a cavity adapted to receive a support member extending from said drive mechanism. In one embodiment, the first cavity is a blind hole having a predetermined depth from the first end. Preferably, the depth is at least about 1.125 inches. The cavity may be tapered, becoming progressively smaller in a direction away from the first end. The retractor blade may have a second cavity adapted to receive a second support member extending from the drive mechanism.

Another aspect of the present invention involves a surgical retractor blade having a polymeric body having a channel adapted to engage one side of an incision in a patient and a rail extending along at least a portion of the polymeric body. The surgical retractor blade is preferably removably attachable to a drive mechanism. Preferably, the rail has a

top portion and bottom portion, the bottom portion having a narrowed region adjacent the top portion thus forming first and second tabs on said top portion. Preferably the rail is curved along its length. The surgical retractor blade may have a cavity, preferably in the form of a tapered hole, adapted to receive a support member extending from a drive
5 mechanism.

The surgical retractor may further include a plurality of open slots for receiving a suture therein. The open slots preferably have an internal wall and a suture locking member having a fixed end and a free end, the free end engaging the internal wall so as to clamp a suture placed between the free end and the internal wall. Preferably, the suture
10 locking member is substantially rigid and pivots about its fixed end. The invention may also include a spring member biased against the suture locking member to forcibly urge the free end towards the internal wall.

In one embodiment of the retractor blade, at least one of the open slots has a first slot section which bifurcates into a second slot section and a third slot section.
15 Preferably, each of the second and third slot sections has an internal wall and a suture locking member having a fixed end and a free end, the free end engaging the internal wall so as to clamp a suture placed between the free end and the internal wall.

In a preferred embodiment, the retractor blade may include a soft tissue retainer for covering or retaining the soft tissue surrounding the incision site. In a preferred
20 embodiment, the soft tissue retainer may be a flexible polymeric flap extending from the body of the retractor blade. The polymeric flap is adapted to flexibly engage and soft tissue and fat to keep them away from the platform area of the retractor body. The

flexible polymeric flap is preferably injection molded over a portion of the retractor blade body.

These and other features of the present invention will become more fully apparent from the following description and appended claims.

The present invention involves surgical instruments for accessing and stabilizing the heart and methods for their use. The present invention may involve a retractor system or assembly for accessing the heart. The present invention may also include a mount that allows various instruments to be easily positioned within the surgical working space, locked or secured into a desired position for the duration of a particular surgical procedure, and then easily and safely removed from the working space. According to a preferred embodiment the instrument may be a device to facilitate stabilization of the heart during coronary surgery.

OC-25205.1

coronary artery bypass graft (CABG) operation which has been specially developed to facilitate completion of an anastomosis, typically between a target artery and a bypass graft or source artery, without requiring cardiac arrest such as cardioplegia or fibrillation and without cardiopulmonary bypass (CPB). Further, although the instruments for
5 accessing and stabilizing the beating heart can be applied in a number of different surgical contexts involving various incisions and surgical approaches to the heart as are known in the art, the instruments and devices described herein are most advantageously employed in a CABG procedure wherein the heart is accessed through only one or two minimally invasive incisions in the chest.

10 Although the particular source vessel and target artery of the anastomosis are determined clinically, a common minimally invasive bypass procedure on the beating heart includes an anastomosis which forms a connection between the left internal mammary artery (LIMA) as the source artery, and the left anterior descending artery (LAD) as the target artery. To complete the anastomosis, the surgeon must dissect a
15 portion of the LIMA by separating it from the internal chest cavity. Once dissection of the LIMA is achieved, the surgeon may attach the dissected LIMA to the target coronary artery, i.e., the LAD by way of creating an anastomosis.

In this example, the present invention may involve a number of discreet components that facilitate access to the anastomosis site, allow various instruments or
20 devices to be maneuvered and secured in place, and provide stabilization of the heart. The retractor of the present invention may be used to provide access to the anastomosis site of the target artery on the heart itself. The various stabilizer embodiments of the present invention may be used to stabilize the beating heart during at least the portion of

the procedure during which the surgeon completes the anastomosis of the LIMA to the LAD. The mount of the present invention may be used to facilitate convenient manipulation of the stabilizer, and other instruments or devices, to their desired position and allows the devices to be secured in that desired position. Although the LIMA to LAD anastomosis is provided as one example, it is readily appreciated that the techniques and instruments described herein may be applied to other procedures depending on the clinical diagnosis and the patient's anatomy.

Although each component of the present invention may be used separately with great benefit, the components are preferably used in unison to provide a surgical system which provides an unobstructed and organized surgical field, exceptional instrument maneuverability and access to the heart facilitating total revascularization of the heart if required, and effective vessel stabilization during the anastomosis procedure. Although the present invention will have application whether access to the heart is achieved by way of a full-sternotomy, mini-sternotomy, para-sternotomy, thoracotomy or other known approach, the exemplar embodiments described below will be generally described with reference to a coronary artery bypass procedure using a mid-sternal approach.

Referring to the figures wherein like numerals indicate like elements, an exemplar surgical system for performing a mid-sternal surgical procedure on the beating heart is illustrated in Figure 1 and includes retractor assembly 10, mount assembly 20 and stabilizer assembly 30.

Retractor assembly 10 generally includes a pair of opposing blades adapted to engage opposite sides of a sternal incision, or other incision, and a drive mechanism constructed to force the blades, and thus the sternum apart. Using the drive mechanism,

the sternum may be spread to the desired opening, thus providing the desired access and direct visualization of the thoracic cavity. If desired, the heart may be positioned or oriented to best present the target vessels for anastomosis. This positioning may be established, for example, through the strategic placement and tensioning of sutures in the pericardial sac, by appropriately placing the patient in the Trendelenburg position, or by
5 using a heart positioner in the form of a strap or pad or the like.

Once the target vessel is in the desired position, at least one component of stabilizer assembly 30 is brought into contact with the beating heart adjacent the target site of the anastomosis. The surgeon then applies a stabilizing force to the beating heart
10 via the stabilizer assembly 30 which may then be fixed in place, preferably to the retractor assembly 10 by way of mount assembly 20. The stabilizing force supplied by the stabilizer assembly substantially eliminates movement of the heart in the area of the anastomosis so that the surgeon may accurately and efficiently perform the required anastomosis (or other surgical procedure). After the anastomosis has been completed, the
15 stabilizing force is released and the contacting component of stabilizer assembly 30 is removed from the anastomotic site.

Each of the principal components, the preferred surgical system, and their methods of use are separately described in detail below. A preferred retractor according to the principles of the present invention is described below with reference to Figures 2-
20 12. A preferred stabilizer or instrument mount according to the principles of the present invention is described below with reference to Figures 13-32. Preferred stabilizer embodiments according to the principles of the present invention are described below with respect to Figures 33-44. A preferred surgical system and methods for performing a

coronary artery bypass on a beating heart according to the principles of the present invention is described below with respect to Figure 45.

The Retractor

According to the principles of the present invention, the retractor generally involves a drive mechanism and a pair of opposing blades adapted for insertion into an incision and for engaging opposite sides of the incision. The drive mechanism functions in some manner to urge the opposing blades apart, thus forcing opposite sides of the incision open to allow surgical access through the incision. For purposes of performing a coronary artery bypass, the incision may be any suitable incision which provides the desired access to the thoracic cavity, and more specifically a desired area of the heart. For purposes of example only, the retractor of the present invention will be described with respect to a mid-sternal incision, however skilled artisans will recognize that many aspects the invention are equally applicable to other surgical approaches to the heart, for example, by way of a thoracotomy, or other suitable access approach.

When the heart is accessed by way of an incision through all or a portion of the sternum, the opposing blades are adapted to be inserted into and engage opposite sides of a sternal incision such that the severed sternum may be forced apart by the action of the opposing blades to create a working space for operating on the heart. Typically, the drive mechanism is constructed to spread the opposing blades apart in a generally parallel fashion, however, the parting motion may also have a significant curvilinear or angular component as well.

In one embodiment, the blades may be permanently, integrally, or inseparably formed with a drive mechanism. Preferably however, at least a portion of the blades are

separable from the drive mechanism. That is, at least some of the features and functions associated with the retractor blades are allocated to a structural component which is separate, separable, or otherwise detachable from the drive mechanism. The separate component and the drive mechanism may be manufactured independently and then
5 subsequently assembled at the factory or, more preferably, at the point of use.

A retractor construction having a separable component allows the features and functions of the drive mechanism to remain separate from the remainder of the retractor assembly and vice versa. This allows a greatly simplified or depopulated drive mechanism and allows the separable component to have a much more sophisticated
10 construction with increased features and functionality. Accordingly, the simplified drive mechanism, which is typically required to be made from a hardened steel, is easier and more economical to manufacture and easier to maintain, clean and sterilize post surgically. Moreover, the separate component can be economically made from materials or processes that allow for the intricate structural features which provide superior
15 functionality.

In a preferred embodiment, the drive mechanism is constructed to be resterilized and reused a relatively large number of times, and the feature-rich separate component is constructed to be disposable, i.e. discarded after a single surgical use. Thus, the depopulated drive mechanism, which will be used over and over, can afford to be
20 constructed to be quite robust with a view to materials and manufacturing processes that will support the rigors of such extended surgical service. The separable component, free from the typical functional requirements of the drive mechanism and the service requirements of extended surgical re-use, may preferably be constructed from any

number of engineering materials to produce an economical component having the desired features and which may be discarded after a single use if desired.

In a preferred embodiment, retractor assembly 10 comprises a drive 12 and first and second platform blades 14 and 16 detachably connected to drive 12, as illustrated in Figure 2. Preferably first platform blade 14 and second platform blade 16 each have one or more channels or engaging members 18 adapted to engage opposite sides of an access incision. Activation of drive 12 forces apart first and second platform blades 14 and 16 thereby causing engaging members 18 to correspondingly force the incision open to provide access to the desired surgical site.

In the example of a sternal approach to the heart, engaging members 18 are adapted to engage each side of the incised sternum to reliably hold and engage the sternum as the sternum is forced open to expose the thoracic cavity and ultimately the heart. As best seen in Figure 9, which illustrates a cross-section of second platform blade 16, engaging member 18 is generally in the form of a channel or the like, preferably having a U-shape, curved shape, or other shape suitable for engaging the incised sternum.

Preferably, engaging member 18 generally has a concave interior profile 17 for engaging and holding the sternum and a corresponding convex exterior profile 19 that is relatively smooth so as not to interfere with other surgical instruments, snag sutures or create other such difficulties. The engaging members 18 are preferably constructed to have sufficient strength to withstand the loads required to spread the sternum yet maintain a suitably low profile to facilitate easy insertion into the access incision and to require as little space within the working incision as possible.

It may be desirable to provide engaging members 18 with features to reduce trauma to the incision site, increase the traction against the sides of the incision, or both. A thin pad or layer of non-slip or atraumatic material (not shown) may be fixed, by way of an adhesive or other suitable fastening technique, to the interior profile 17 if desired to
5 reduce slippage and trauma to the severed sternum or surrounding tissue. Alternatively, the desired features may be integrally fabricated into engaging members 18. For example, when platform blades 14 and 16 are injection molded components, traction features such as raised bumps, ribs, indentations, or the like can be molded integral into engaging members 18.

10 Referring to Figures 2-6, drive 12 is preferably constructed to force the platform blades apart in generally opposite directions. Any type of drive mechanism which provides the desired separating action of the blades may be suitable. A common, substantially straight-line parting motion may be provided by a ratchet or rack arrangement as is generally known in the art. Figure 3 illustrates a preferred drive 12
15 which involves a bar 15, moveable housing 22 and handle assembly 24 which facilitates movement of moveable housing 22 relative to bar 15. A first end of first blade 14 may be operably attached to moveable housing 22 and second blade 16 to bar 15.

In a preferred embodiment, bar 15 is a substantially rigid bar having a stationary or fixed housing 21 assembled thereto and thus forming bar assembly 23. Fixed housing
20 21 may be fastened to one end of bar 15 using one or more mechanical fasteners, an interference fit, suitable adhesive or bonding compounds, welding, or any other suitable fastening technique. A first end of second blade 16 is preferably operably attached to fixed housing 21. As with moveable housing 22, fixed housing 21 may be of any

configuration which provides for the structural attachment of first and second platform blades 14 and 16.

Bar 15 preferably includes a number of teeth 13 evenly spaced along at least a portion of its length. Teeth 13 may have substantially parallel side portions 11 and may have radiused tops 25. The exterior edges of teeth 13 may be broken or radiused or have a chamfer 26 as shown. Handle assembly 24 preferably includes a means for engaging teeth 13 so as to drive moveable housing 22 relative to bar 15 to any desired position under load where it remains so positioned against the load without need for any applied input or holding force. The means for engaging teeth 13 could be any suitable gear, ratchet, cog or like mechanism. Bar 15 may also be adapted and used for receiving an instrument mount, such as those described in detail below.

In a preferred embodiment, moveable housing 22 is driven using one or more drive pins which may successively engage teeth 13 in a cogging manner. Handle assembly 24 includes drive handle 29 connected to first and second cylindrical drive bearings 31 and 32. Drive bearing 31 preferably has a raised boss 34 extending from one end to which drive handle 29 may be pivotally connected by way of pin 33. At the opposite end, drive bearing 31 has first drive pin 27 and second drive pin 28 extending therefrom and terminating at second drive bearing 32. First and second drive bearings 31 and 32 are spaced apart a distance 35 which is selected to be slightly greater than the thickness 38 of bar 15 such that a portion of bar 15 may be received between first and second drive bearings 31 and 32. The outside diameters of drive bearings 31 and 32 are selected so as to fit within guide holes provided in moveable housing 22. For example,

the outside diameter of second drive bearing 32 is sized to accurately rotate within guide hole 36.

Moveable housing 22 has a bore 37 extending therethrough for receiving bar 15. Bore 37 generally has a shape corresponding to the dimensions of the cross-section of the portion of the bar 15 which is to pass through bore 36. With handle assembly 24 properly positioned within the guide holes provided in moveable housing 22, it may be assembled to bar 15 by placing the end of bar 15 within bore 36 and turning handle 29 such that first and second drive pins 27 and 28 become engaged with teeth 13. Once assembled in this manner, moveable housing 22 may be forced one way or the other along the length of bar 15 by turning handle 29, and thus drive bearings 31 and 32, to cause first and second drive pins 27 and 28 to progressively engage teeth 13 along bar 15.

As mentioned above, first and second platform blades 14 and 16 may be removably assembled to moveable housing 22 and fixed housing 21, respectively. Platform blades 14 and 16 may be attached in any suitable fashion including, for example, threaded connections or other mating features on the platform blades and housings themselves, ordinary or specialized mechanical fasteners, and cam or latching mechanisms adapted to secure the platform blades to the housings. In a preferred embodiment, both moveable housing 22 and fixed housing 21 are constructed with features that engage, secure and support first and second platform blades 14 and 16 in an operable position on drive 12, thus providing an assembled retractor 10 which is ready for surgical use.

Referring to Figures 7 and 8, second platform blade 16 is shown before and after assembly onto fixed housing 21. Preferably, at least one of the platform blade 16 or the

fixed housing 21 has an extending protuberance, post or like feature which can be
receivably engaged by the other of the platform blade or housing. In a preferred
embodiment, fixed housing 21 is preferably constructed to have a latch post 42 adapted to
be received within latch post cavity 45 provided in platform blade 16. Latch post 42 may
5 have a hole, notch, protuberance, or other feature formed therein which may be engaged
in any convenient manner by the platform blade 16 so that platform blade 16 becomes
releasably locked in place for use.

In a preferred embodiment, latch post 16 has a notch which defines latch surface
51 and stop surface 52. Platform blade 16 has a latch member 48, best seen in Figures
10 11A-11A, having a latch body 50 constructed with surfaces 53 and 54 for engaging latch
surface 51 and stop surface 52 respectively. Generally transverse to latch post cavity 45,
platform blade 16 has a latch body cavity 56 having an opening towards upper surface 57
of platform blade 16 for receiving latch body 50 of latch 48.

Latch 48 is preferably constructed to engage and disengage latch post 42 by
15 manual rotation of latch knob 49. Latch body 50 includes cylindrical portion 55 which
provides for controlled rotation within latch body cavity 56. Latch body 50 may be
biased towards the engaged position shown in Figure 8 by way of any suitable spring
element. Preferably, latch post 42 is provided with an angled tip 43 having a lead-in
angle 44 which allows angled tip 43 to slide against second engaging surface 54 as latch
20 post 42 begins to be received within latch post cavity 45. As latch post 42 is advanced
further within latch post cavity 45, angled tip 43 causes latch 48 to rotate out of the way
about cylindrical portion 55. Near the end of the advancement of latch post 42 within
latch post cavity 45, the angled tip is advanced beyond latch body 50, and latch 48 (which

is biased towards an engaged position) rotates into the engaged position with second engaging surface 54 biased against stop surface 52.

With latch 48 and latch body 50 snapped into the engaged position, any separating force encountered between platform blade 16 and fixed housing 21 is resisted by action of first engaging surface 53 against latch surface 51. With this configuration, the reaction force at first engaging surface 53 is advantageously borne by latch body 50 primarily in compression. Thus, since the loading is primarily compressive in nature, a high strength material is not required, and latch 48 can be made from standard engineering polymers, for example, such as polycarbonate.

When it is desired to remove platform blade 16 from drive 12, the operator simply turns latch knob 49, causing latch body 50 to be placed in a disengaged position relative to latch post 42. With latch 48 disengaged, latch post 42 of fixed housing 21 is free to be removed from latch post cavity 45 of platform blade 16. As is apparent from the Figures, a mirror image of the latch assembly described with reference to platform blade 16 and fixed housing 21 is provided to releasably attach platform blade 14 to moveable housing 22.

When the retractor assembly is used to gain access to the thoracic cavity, a good deal of force must be generated to create the desired opening. For example, a separating force in excess of 100 pounds may be required to be generated at each engaging member 18 to achieve the desired separation of a particular sternum. Such loads must be carried by the engaging members and transmitted to drive 12 by way of platform blades 14 and 16. Since platform blades are preferably made from a suitable engineering polymer (for example, a glass filled thermoplastic polyurethane resin), it may be desirable to provide a

reinforcing member for each of platform blades 14 and 16 to ensure that platform blades 14 and 16 will not break or otherwise rendered inoperable as a result of the loads encountered during use.

Although the reinforcing members may be a permanent or removable members
5 within the platform blades themselves, the reinforcing members are preferably one or more substantially rigid members extending from each of the fixed housing 21 and the moveable housing 22. In a preferred embodiment, fixed and moveable housings 21 and 22 have a pin extending therefrom which may be received within a mating cavity within first and second platform blades 14 and 16. The pin operates to spread the load
10 developed in the mechanism over a larger internal area within the platform blades 14 and 16 and reduces the effective beam length of unreinforced platform blade material subjected to the operating loads. The pin may be straight pin 40' illustrated in Figure 3. More preferably, fixed and moveable housings 21 and 22 have tapered pins 40 and platform blades 14 and 16 have mating tapered cavities 41 for receiving tapered pins 40.
15 The tapered construction tends to allow the user to easily align pin 40 with cavity 41 and allows the pins 40 to fit relatively snugly within cavities 41 without significant binding during insertion that could otherwise occur between elongate pins and mating cavities which are designed to be very close fitting.

To provide sufficient load bearing reinforcement, the reinforcing pins 40 are
20 preferably constructed of a substantially rigid material, such as steel, and are preferably at least about 0.75 inches long, more preferably at least about 1.125 inches long, and most preferably between about 1.25 inches to about 2.25 inches long. In a preferred embodiment, reinforcing pins 40 are made from AISI 420 stainless steel having a length

of about 1.5 inches, an outside diameter near the housing of about 0.25 inches, and a 2 degree taper angle decreasing towards the free end of the reinforcing pins 40.

In the preferred embodiments just discussed, platform blade 16 can be removed from drive 12 with a substantially straight-line relative motion as indicated by arrow 46.

5 This engagement action not only provides for simple and intuitive assembly in the operating room, but also represents a significant safety feature. Under certain rare circumstances, for example where the drive through neglect or misuse has become sufficiently damaged during use that it is unable to close and disengage from the sternum, an extremely dangerous situation can be created for the patient. In such exigent
10 circumstances, the configuration described above may allow the drive to be separated from the in situ platform blades by releasing the latches and applying a sufficient amount of force in the direction indicated by arrow 46. Once the drive has been removed, the detached platform blades may be easily removed from the patient.

In addition to engaging members 18, detachable platform blades 14 and 16 may
15 incorporate a wide variety of additional features which enhance the performance of the retractor system. For example, one or both of platform blades 14 and 16 may have mounting features to which various instruments used during the procedure can be secured. In the case where a stabilizer is to be secured to a retractor for operating on a beating heart, it is critical to minimize or substantially eliminate the amount of flex and
20 motion attributable to each component and each connection between each component, from the component engaging the beating heart to the component which provides the sternal attachment. To this end, the engaging features 18 which engage the sternum are preferably part of a unitary platform blade structure which also includes mounting

features to which a stabilizer and other instruments can be mounted. Since the mounting features and the sternal engaging features are part of the same component, and therefore there is no mechanical connection between the two, the stability of an attached instrument against the forces of a beating heart is greatly improved.

5 In a preferred embodiment, each of first and second platform blades 14 and 16 include mount features in the form of rails. The rails allow one or more instruments to be positioned at any desired location along the operable length of the rail. Preferably, the rails are oriented in a direction generally perpendicular to the direction of separation, in this case perpendicular to bar 15. The rails may be a recessed feature within the body of
10 platform blades 14 and 16. More preferably, the mounting rails extend upwardly from the body of platform blades 14 and 16.

Referring to Figures 7-9, right platform blade 16 has rail 60 extending over at least a portion of the length of platform blade 16. Rail 60 may have a top portion and a bottom portion having a narrowed region adjacent said top portion. In one embodiment,
15 Rail 60 preferably has a T-shaped cross-section. The T-shaped configuration has a top portion 61 and a narrowed portion 62, thus forming mounting tabs 63 and 64 which can be gripped by a number of appropriately constructed mounts.

The rail may be straight, curved, or a combination of straight and curved portions. Preferably, at least a portion of the T-shaped rail is curved in a manner which more
20 closely follows the profile of the access or incision site (as seen, for example, see Figure 45). In a curved rail configuration, instruments extending perpendicular to a generally central axis 67 of rail 60 will naturally point more towards a central area between the platform blades 14 and 16, and thus may require less positional adjustment or

manipulation from their normal, natural or beginning position. In addition, all or a portion of top portion 61, and more specifically mounting tabs 63 and 64, may be tilted or angled inwardly at an angle 65 as shown.

Platform blade 16 may be also be provided with a number of suture holders or stays which can be used to organize or capture various sutures used in the course of a particular surgery. Since certain sutures are placed near the beginning of a CABG procedure, such as pericardial sutures used to position the heart, the placement of the suture stays in a manner which does not interfere with subsequent procedures and instruments is an important aspect of the present invention. Preferably, the suture stays are positioned such that placing and manipulating the sutures or the various instruments and instrument mounts employed during surgery can be accomplished without interfering with each other. Preferably, the location of the suture stays position the sutures below the level of the mounting tab 63 and 64 so that a mating instrument mount may traverse the entire operable length of rail 60 without interfering with the sutures.

Rail 60 may have one or more grooves, channels, slots or passageways for receiving a suture. In addition, a suture lock may be provided in the rail or elsewhere on platform blade 16 so that the suture may be fixed in place. To accommodate the use of pericardial sutures, which are often subjected to a significant amount of tension when used to position the heart, the suture locks must be adapted to hold the suture material even while under a significant amount of tensile loading.

In a preferred arrangement for organizing and locking sutures, and in particular tensioned pericardial sutures, rail 60 has at least one open slot or passageway formed therein for receiving the free end portions of a surgically placed suture. The passageways

preferably extend across rail 60 and have a depth which allows the suture to lay at an elevation sufficiently below mounting tabs 63 and 64 so as not to interfere with an instrument mount sliding along rail 60. In a preferred embodiment the passageways extend through at least a portion of narrowed portion 62. Thus, the height 66 of narrowed
5 portion 62 may be selected not only to provide sufficient space for a desired instrument mount to attach, but also to ensure that mounting tabs 63 and 64 are sufficiently raised above the surrounding features of platform blade 16 so that an instrument mount may be positioned and repositioned along rail 60 without disturbing or disrupting the sutures within the various passageways.

10 The passageways may be a single channel for receiving both free ends of a surgically placed suture or each end may have a separate channel. In a preferred embodiment, rail 60 has a number of bifurcated channels 70 at predetermined intervals along its length. Referring to Figure 10, bifurcated channel 70 has a single entrance
15 channel 71 which bifurcates into first and second exit channels 72 and 73. Entrance channel 71 and either one of exit channel 72 or 73 can be used in the same manner as a single channel, with both free ends 76 and 77 being routed together. Alternatively, both suture ends may be received within entrance channel 71 and then separated, one end within exit channel 72 and one end within exit channel 73.

A means for clamping the suture against movement within the suture channels
20 may be provided on any of entrance channel 71 or exit channels 72 or 73. Preferably, suture locks are provided on each exit channel 72 and 73. This allows the surgeon to positively identify and unlock a desired suture end for further tension adjustments or other manipulation without unlocking or loosening the other end of the suture. In

addition, placing each suture end 76 and 77 in separate exit channels 72 and 73, each with a dedicated suture lock, increases the maximum amount of tension that can be applied to a given suture. Exit channels 72 and 73 may have recesses 74 and 75, respectively associated therewith for receiving a suture lock adapted to secure the suture material
5 within the channels.

A preferred suture lock 80 is illustrated in Figures 10 and 12. Suture lock 80 has a relatively rigid body 83 having a fixed or pivot end 81 which allows body 83 to pivot within the mating profile of recess 74 or 75. Pivoting the body 83 about pivot end 81 selectively engages and disengages free end 84 against the wall 78 of exit channel 72 or
10 73. Alternatively, suture lock 80 may be made from a more flexible material which, by nature of the elastic properties of the material, tends to flex about its fixed end instead of rotate. In a preferred embodiment, fixed or pivot end 81 is substantially cylindrical and recesses 74 and 75 have mating cylindrical surfaces.

Preferably, the suture lock is angled relative to the wall 78 so that it is self-locking
15 in one direction. That is, the suture ends 76 or 77 (or both) operate on the free end 84 in such a way as to force it towards wall 78, and thus against the suture material, in proportion to the tension, T encountered by suture ends 76 or 77. Thus, within practical limits, the higher the tension the harder free end 84 will press or bite against the sutures placed therein. Conversely, when the suture ends are pulled in the direction indicated by
20 arrow 79, the suture forces tend to pivot body 83 about pivot 81 such that free end 84 is rotated away from wall 84 allowing the suture to move relatively freely. Preferably, angle 79 between body 83 and wall 78 is nominally about 1 degree to about 30 degrees, more preferably about 5 degrees to about 15 degrees, most preferably about 10 degrees.

Of course, angle 79 is greater as body 83 pivots to accept a suture placed within the suture channel.

5 Suture lock 80 may be biased towards the locked position, preferably using a small spring between the suture lock and the recess 75. In a preferred embodiment, a piece of resilient closed cell foam 85 is fixed to body 83 to provide the desired biasing effect. Free end 84 may optionally have a number of teeth or ridges 82 to ensure acceptable traction against the suture material.

Platform blades 14 and 16 may also be provided with soft tissue retainers to help control and retain the incised tissue and fat in the immediate vicinity of the blades.

10 Referring to Figures 8 and 9, platform blade 16 includes integrally attached tissue retainer 85. Tissue retainer 85 is generally at a small distance 88 above the top of the engaging members 18. Tissue retainer 85 may be made from a flexible material, such as an elastomer, preferably a polyurethane elastomer having a durometer in the range of about 45 to about 75 Shore D, more preferably about 55 Shore D. In a preferred embodiment
15 tissue retainer 85 is injection molded over the platform blade to form a permanent and inseparable assembly. Tissue retainer 85 may have a raised outer lip 86 and optionally having a plurality of slots 87 formed therein to receive and organize any loose suture ends. Tissue retainer 85 ensures that the tissue surrounding the access incision does not interfere with the operation of rail 60 or the suture holders and also provides a convenient
20 location for attaching surgical drapes of the like without interfering with the operation of the retractor assembly.

Although some of the features of the present invention have been described, for illustration only, with respect to only one of the platform blades 14 and 16, it should be

apparent that both platform blades 14 and 16 may have similar or identical features.

Although not necessarily so, first platform blade 14 and second platform blade 16 are preferably substantially mirror images of each other.

The retractor assembly just described, provides a simplified drive mechanism for use in conjunction with multi-featured platform blades. In addition, a number of different platform blades may be provided for use with a single drive, for instance, tailored to different sized anatomy or the specifics of different surgical procedures. Thus, a number of platform blade configurations can be provided to an operating room and, based upon pertinent prevailing clinical factors, the proper configuration can be selected, mounted to drive 12, and used as described above to provide access to a desired location. Also, with the modular configuration new features and advancements can be rapidly incorporated into the platform blades and immediately introduced for use with existing simplified drives already in place in the operating rooms.

The platform blades themselves represent a surgical platform that allows instruments to be mounted and stabilized in virtually any position, even over already placed and secured sutures from the surgical site accessed by the retractor assembly. Described below are preferred instrument mounts for use in conjunction with rail 60 to secure a beating heart stabilizer or other instruments such as heart positioners, saline or medical air blowers, suction devices, surgical clamps, or vessel occluders.

The Instrument Mount

Referring to Figure 13, a preferred instrument mount assembly 20 is shown for mounting an instrument, such as stabilizer assembly 30, to an instrument mounting rail such as described above with respect to rail 60 of platform blades 14 and 16. Mount

assembly 20 includes mount base 115 having features to secure mount assembly 20 at a desired position on an appropriately configured mating rail or other suitable structure and includes a shaft locking mechanism for controlling and securing an instrument shaft in a desired position and orientation.

5 One important aspect of instrument mount assembly 20 is to provide the necessary degrees of freedom to allow the instrument to be easily maneuvered to whatever position may be required by a particular procedure. As discussed above, an additional aspect with respect to stabilizing the beating heart is to eliminate or minimize the flex or motion attributable to the various components and connections of instrument
10 mount assembly 20. As will be discussed in more detail below, instrument mount assembly 20 is uniquely suited for use in stabilizing the beating heart because it allows sufficient degrees of freedom to easily manipulate the position of an instrument secured thereto, allows the degrees of freedom to be frozen or locked in place and, once locked in place, does not significantly flex or allow movement at any of the mechanical joints or
15 connections.

Instrument mount assembly 20 provides a number of different controllable joints that, when in a released condition, allows motion in one or more predetermined directions or about one or more degrees of freedom. Although instrument mount assembly 20 may be used to secure any mounting shaft configuration from straight or curved substantially
20 rigid shafts to multi-link or segmented ball and socket type shafts which are relatively flexible until themselves locked in some manner at each joint along the shaft length, it is most advantageously constructed to provide the joints or connections required to position an instrument having a straight or curved rigid shaft.

In a preferred embodiment, instrument mount assembly 20 has three releasable joints or connections for controlling the location and position of the instrument mount assembly and instrument attached thereto. The mount base may be positioned at a desired location along an appropriate rail and secured by rail grips 114 and 116. The position and orientation of the instrument is then determined by ball joint (or ball and socket joint) 112 between mount base 125 and mount body 110, a rotational joint 157 between mount body 110 and shaft hub assembly 160, and a shaft clamping mechanism within shaft hub assembly 160 which may allow translation, rotation, or both of shaft 3 relative to shaft hub assembly 160.

Ball joint 112 is preferably of the ball and socket type having 3 rotational degrees of freedom. Rotational joint 157 allows rotation of shaft hub assembly 160 about axis 121 as indicated by arrow 113. The shaft clamping mechanism allows translation of instrument shaft 3 as indicated by arrows 111 as well as rotation about the shaft itself as indicated by arrow 117. As will be discussed later, a further ball-joint type connection 201 may be employed between shaft 3 and the particular end-effector of the instrument.

Instrument mount assembly 20, having the particular joints and connections identified above, allows all the required areas of the heart to be conveniently and intuitively accessed by a stabilizer connected to one end of a substantially rigid shaft. Certainly, instrument mount assembly 20 could be provided with more or less degrees of freedom for maneuvering a particular instrument. For example, to add additional degrees of freedom rotational joint 157 could be replaced with a ball joint and to eliminate degrees of freedom shaft 3 could be keyed within shaft hub assembly 160 or ball joint 112 could be replaced with a rotation only joint. However, it should be noted that

excessive degrees of freedom may tend to make instrument adjustment increasingly difficult and cumbersome to control while too few degrees of freedom may not allow the instrument to be easily placed in the desired position or orientation.

In one embodiment, the various joints and connections are locked into a desired position by way of a series of knobs. The degrees freedom provided by ball joint 112 is locked by activation of top mount knob 120. Both rotational joint 157 and the shaft clamping mechanism of shaft hub assembly 160 is locked in place by the activation of side mount knob 118. Base 125 is locked in position on the rail by activation of mount lever 122. Ball joint 201, as will be discussed in greater detail below, may be locked in position by activation of knob 504. This particular sequence of knobs used to lock down the degrees of freedom associated with instrument mount assembly 20 tends to allow the user greater precision in positioning the instrument because degrees of freedom unnecessary to a particular desired maneuver of the instrument can be locked down. Most commonly, mount body 110 is placed at a desired angle or orientation and then fixed in place by locking ball joint 112, leaving final adjustment to take place using rotational joint 157 and the shaft movement allowed by the shaft clamping mechanism of shaft hub assembly 160.

Figures 14-20 show in greater detail the various mechanisms which lock and release the joints or connections associated with instrument mount assembly 20. Figure 14 shows an exploded assembly illustration of instrument mount assembly 20.

Instrument mount assembly 20, and more specifically mount base 125 to which all the other components are ultimately secured, is preferably constructed to engage and lock in position on a rail or other suitable feature.

Preferably, instrument mount assembly 20 has a fixed rail grip 114 adapted to engage mounting tab 64 of rail 60 and a moveable rail grip 116 adapted to engage mounting tab 63 or rail 60. Rail grips 114 and 116 may generally have hook-like features for gripping mounting tabs 63 and 64. Rail grip 114 is part of mount base 125 and
5 moveable rail grip 116 is part of articulating hinge member 115, which is pivotally attached to mount base 125 by way of hinge pins 123 and 124, or other suitable fastener. Articulation of hinge member 115 and rail grip 116 in clamping manner towards rail grip 114 on mount base 125 effectively clamps mount base 125 onto rail 60 at mounting tabs 63 and 64.

10 Hinge member 115 may be articulated using any suitable mechanism capable of pivoting hinge member 115 to a closed position and holding it there.. In a preferred embodiment, best illustrated in Figures 15A-17, hinge member 115 includes follower surface 155 which may be acted upon by any suitable cam device to drive hinge member 115 about hinge pins 123 and 124, thus urging rail grip 116 towards rail grip 114.

15 In a preferred embodiment, hinge member 115 is articulated by action of cam 145 having cam surface 152 which acts upon follower surface 155. Cam 145 has a center, C about which cam 145 rotates. Preferably, cam 145 has bore 127, having its central axis coincident with center, C. Mount base 125 may have a cam guide 153 around which bore 127 rides for smooth rotation of cam 45 about center, C. Cam surface 152 has a varying
20 radius, illustrated by exemplar radial lines R_1 , R_2 , R_3 , R_4 , and R_5 . Thus as cam surface 152 is rotated past follower surface 155, from example from R_1 to R_2 , it pushes the follower surface a greater distance away from center, C, thus causing hinge member 115

to pivot about hinge pins 123 and 124, thus causing rail grip 116 to move closer to rail grip 114.

The varying radius of cam surface 152 may be configured to place hinge member 115, and thus rail grip 116 in a variety of positions. A first portion of cam surface 152 may be configured such that follower surface 155 biased against cam surface 152 is placed in an position characterized in that rail grip 116 is sufficiently spaced apart relative to rail grip 114 to allow assembly onto a rail or other structure. A second portion of cam surface 152 has an increasing radius such that rotation of cam 145 moves rail grip 116 towards rail grip 114 to an intermediate position. In the intermediate position, rail grip 116 has been moved close enough to rail grip 114 so that it becomes captured on a rail but remains loose enough to slide along the rail. A third portion of cam surface 152 has an increasing radius such that the rotation of cam 145 moves rail grip 116 further towards rail grip 114 to a completely locked position wherein relative motion between rail grips 114, 116 and the rail is essentially no longer possible.

Cam 145 is generally provided with a handle or lever 122 to allow the user to easily turn cam 145 relative to mount base 125. Cam 145 may be captured onto mount base 125 by operation of retaining hook 150 on cam 145 which rides within exterior groove 151 on mount base 125 on one side, and projection 154 which is engaged below undercut 156 generally opposite to retaining hook 150. Projection 154 also serves to work against undercut 156 to return hinge member 115 to the open position as cam 145 is rotated in the opposite (open) direction. Hinge member 115 preferably has first and second end stops 158 and 159 between which the motion of projection 154 (and thus the

rotation of cam 145) is limited. Cam 145 may also have a protective extended portion or cover 163 which shields the area of groove 151 when assembled over mount base 125.

The assembly of cam 145 and hinge member 115 to mount base 125 is illustrated in Figures 15A and 15B. Cam 145 is placed in position relative to hinge member 115 with projection 154 in place below undercut 156. In roughly that position, cam 145 and hinge member 115 are brought over mount base 125 until bore 127 is properly seated over cam guide 153 and retaining hook 150 is positioned within groove 151. Pins 123 and 124 are then pressed in place through holes provided in both mount base 125 and hinge member 115.

Ball joint 112 is generally created between ball 129 provided at the top of mount base 125 and a socket or mating cavity within mount body 110 adapted to receive at least a portion of ball 129. Preferably ball 129 includes a generally spherical portion, although other curved shapes providing the desired degrees of freedom may also be suitable. Base post 130 extends vertically upward through bore 126 of mount base 125 and vertical passageway 128 of mount body 110 until enlarged end portion 130 become biased against mount base 125. Top mount knob 120 may then be threaded onto threaded shaft 132 whereby mount base 125 and mount body 110, with ball 129 received within mount base 125, becomes captured between top mount knob 120 and enlarged end portion 130.

Continued tightening of top mount knob 120 over threaded shaft 132 forces ball 129

harder against mount body 110 until the friction between mating surfaces on ball 129 and mount body 110 become so great as to effectively resist any relative movement, thus locking ball joint 112.

The assembly of rotational joint 157 and shaft hub assembly 160 are shown in Figure 19. Rotational joint 157 is in the form of a conical clutch formed between frustoconical surface 138 of clutch member 135 and mating frustoconical surface 139 in mount body 110. Shaft hub assembly 160 is generally formed as upper and lower shaft locks 136 and 137 are advanced over shaft grip 140 and against instrument shaft 3 which is positioned between shaft locks 136 and 137 and outer shaft guide 144. As clutch member 135 is received over the outside diameter of grip housing 141 of shaft grip 140 tang 164 becomes engaged between upper shaft lock 136 and lower shaft lock 137 thereby preventing relative rotation between clutch member 135 and shaft grip 140.

Side mount knob 118 having threaded shaft 119 extends through mount body 110 (and consequently through transverse bore 131 in central portion 167 of base post 130), clutch member 135 and into interior threads 142 within grip housing 141 of shaft grip 140. Tightening of side mount knob 118 clamps the assembly together. Thus, translation and rotation of instrument shaft 3 is prevented as shaft grip 140 and clutch member 135 are forced together to clamp or trap instrument shaft 3 between shaft locks 136 and 137 and outer shaft guide 144. Also, relative rotation between frustoconical surface 138 of clutch member 135 and mating frustoconical surface 139 in mount body 110 is prevented as clutch member 135 is forced against mount body 110. One or both of frustoconical surface 138 and mating frustoconical surface 139 may include a number of teeth, ridges, or other features to prevent rotation when clutch member 135 is forced against mount body 110.

So that the shaft does not become too loose as side mount knob 118 is loosened, a minimum amount of friction between instrument shaft 3 and the clamping surfaces 146 of

outer shaft guide 144 is preferably maintained by providing a biasing load against shaft 3.

Referring to Figure 20, shaft biasing member 147 is provided within shaft grip 140 to

maintains a biasing load against shaft 3. Shaft biasing member 147 has a first portion 148

which slides within counterbore 143 in shaft grip 140. Shaft biasing member 147 may

5 optionally have a second portion 149 having external dimensions sized to be received

within the inside diameter of compression spring 133. Compression spring 133 urges end

134 of shaft biasing member 147 against shaft 3 to force shaft 3 against clamping

surfaces 146. The amount of force is selected to allow instrument shaft 3 to be easily

positioned by hand but would generally not allow instrument shaft 3 to slide relative to

10 shaft grip 140 under only its own weight.

Referring to Figure 21 a preferred instrument mount assembly 20 is shown fixed

to a preferred platform blade 16 having rail 60. As discussed above, rail 60 has mounting

tabs 63 and 64 over which rail grips 114 and 116 may be secured. Instrument mount

assembly 20 can be positioned, maneuvered, and removed virtually anywhere along rail

15 60 without disturbing suture 166 locked in place by free end 84 of suture lock 80 below

the operating features of instrument mount assembly 20 within any one of the suture

channels provided in platform blade 16. In addition, rail 60 is placed in close proximity

to engaging member 18 and thus close to the surgical opening into the patient providing a

more direct access to the heart by an instrument mounted to instrument mount assembly

20 20. Since the rail 60 moves in unison with platform blade 16, this relationship between

rail 60 and engaging member 18 is maintained no matter how much or how little platform

blades 14 and 16 have been spread to create the desired surgical opening.

Figures 22A-32 illustrate a preferred embodiment of an alternative instrument mount assembly 220. Preferably, the degrees of freedom available for maneuvering instrument mount 220 is substantially the same as that of instrument mount assembly 20. Instrument mount assembly 220 preferably has ball joint 112 between mount base 221 and mount body 222, a rotational joint 157 between mount body 222, and a shaft hub assembly 227 which allows rotation and translation of an instrument shaft held between shaft grip 226 and clutch member 226 of shaft hub assembly 227. Instrument mount assembly 220, however, has a different mechanism for controlling or locking the various joints and connections and may also provide a means for releasing and removing the shaft from the bulk of the remainder of instrument mount assembly 220.

As just mentioned, the joints and connections themselves are quite similar between instrument mount assemblies 20 and 220. As before, ball joint 112 is a ball and socket configuration created between generally spherical ball 224 provided at the top of mount base 221 and a mating cavity within mount body 222 adapted to receive and slide against at least a portion of ball 224. Rotational joint 157 may be in the form of a conical clutch formed between frustoconical surface 243 of clutch member 225 and mating frustoconical surface 244 in mount body 222. An instrument shaft may be clamped in place within shaft hub assembly 227 by forcing together shaft grip 226 and clutch member 225 thus closing clamp surface 239 of outer shaft guide 233 towards V-shaped channels 273 on shaft locks 231 and 232.

Instead of locking the joints and connections by way of multiple knobs as described above with respect to instrument mount assembly 20, instrument mount assembly 220 preferably uses a mechanism which releases each of ball joint 112,

rotational joint 157, and the shaft clamping mechanism of shaft hub assembly 227 by
activation of a single knob, lever, or other suitable manual interface. Generally speaking,
this is accomplished by utilizing the clamping motion required to lock one or more of the
joints or connections along a first axis to also lock the remainder of the joints or
5 connections along remaining axes.

In a preferred embodiment, ball 224 of mount base 221 is locked in place relative
to housing 222 by operation of base post 230. Base post 230 is assembled through mount
base 221 and mount body 222 from the bottom until bottom flange 259 (see Figure 27) is
resisted against mount base 221. At the top of base post 230 is upper link portion 256
10 having pivot hole 257. Cam 235 is attached through pivot hole 257 at off-center link
pivot 238 using a pin or other suitable fastener and is supported by contact surface 236
associated with mount body 222. Contact surface 236 may be an integral feature of
mount body 222 or may be in a separate mount body cover 254 which may be selected to
have superior wear characteristics.

15 With cam 235 in a closed position, as shown in Figure 24, link pivot 238 is drawn
to its maximum distance 251 (or slightly less than the maximum if the cam is constructed
to rotate over center) from contact surface 236 thus increasing the clamping force
between mount body 222 and ball 224 as the assembly is clamped between cam 235 on
the top and bottom flange 259 on the bottom. With cam 235 in the closed position, ball
20 joint 112 is effectively locked.

By rotating cam 235, by way of handle 237, to an open position as illustrated in
Figure 25, link pivot 238 is withdrawn to a position closer to contact surface 236 at a
distance 252, thus reducing or relaxing the clamping forces between mount body 222 and

ball 224 of mount base 221. With cam 235 in the open position, the friction at ball 224 is reduced to a level that allows the user to easily manipulate mount body 222 relative to mount base 221.

Mount base 221 may have an insert 253 secured in the bottom thereof against
5 which bottom flange 259 is caused to seat as upper link portion 256 is drawn upwards by operation of cam 235. Preferably, insert 253 includes recess 255 for receiving compression spring 248 captured about base post 230. Compression spring 248 operates between insert 253, and thus mount base 221, and bottom flange 259 to bias base post 230 towards the unlocked position.

10 That same motion of base post 230, created by operation of cam 235, is preferably also used to lock both rotational joint 157 and the instrument shaft clamping mechanism of shaft hub assembly 227. Instead of using a threaded shaft to clamp instrument mount assembly along this axis as did the previous embodiment, instrument mount assembly
20 220 preferably utilizes tie pin 240 which is driven in the direction of arrow 245 causing shaft grip 226 and clutch member 225 to be forced together to clamp an instrument shaft placed therein and also causing frustoconical surface 243 of clutch member 225 to forced against frustoconical surface 244 in mount body 222.

Tie pin 240 preferably has a generally cylindrical back portion 261 and a front portion which is connected in some manner to shaft grip 226. Preferably, the front
20 portion includes forward extending first and second flexible prongs 262 and 263. Cylindrical back portion 261 is slidably received within blind hole 272 of release button 242 and is preferably biased in the unlocked direction indicated by arrow 270 by compression spring 247 positioned within blind hole 272 behind tie pin 240.

Tie pin 240 is preferably driven in the direction of arrow 245 by the movement of base post 230 which is assembled in the space between first and second prongs 262 and 263 of tie pin 240. Preferably, base post 230 has an angled cam or ramp 258 that engages back wall 269 at the base of first and second prongs 262 and 263. As base post 230 is drawn upwards in the direction of arrow 271 by cam 235 from the open position of Figure 25 to the closed position of Figure 24, ramp 258 progressively forces back wall 269, and thus tie pin 240, in the direction of indicated by arrow 245.

Tie pin 240, connected at its front end to shaft grip 226, locks an instrument shaft in place and locks rotational joint 157 in the same manner as did threaded shaft 119 of instrument mount assembly 20. In sum, tie pin 240 urges shaft grip 226 towards clutch member 225 and mount body 222. The movement of shaft grip 226, having tang 236 engaged between upper and lower shaft locks 231 and 232 of clutch member 225, closes together in a clamping fashion surfaces 239 on shaft grip 226 and V-shaped channels 273 on clutch member 225. At the same time, shaft grip 226 pushes against clutch member 225 to force frustoconical surface 243 against mating frustoconical surface 244 with sufficient force to frictionally lock the surfaces together, thus preventing relative motion therebetween.

The operation of cam 235 has been described as generally moving between an open position, in which the various joints and connections of instrument mount assembly 220 are free to be easily manipulated about their respective degrees of freedom, and a closed position in which the joints and connections resist any relative movement and are thus effectively locked in position. However, the outer cam profile of cam 235 operating against contact surface 236 may be given a profile that has one or more intermediate

positions such that link pivot 238 is placed at an intermediate distance from contact surface 236. In an intermediate position, the joints and connections may be in a stiffened or partially locked state which allows some positional and orientational manipulation with somewhat higher operator forces than the completely released condition. In addition, 5 the action of base post 230 may be such that ball joint 112 becomes fully locked before tie pin 240 has completely locked the remaining degrees of freedom. Thus, cam 235 may have a completely released position where manipulation about all degrees of freedom is easily accomplished, an intermediate position in which only ball joint 112 is fully locked and the remaining degrees of freedom are unlocked or may be partially locked, and final 10 closed position in which all degrees of freedom are locked.

Instrument mount assembly 220 may optionally be provided with a release mechanism allowing shaft grip 226, and thus the instrument shaft slidably assembled therein, to be released from instrument mount assembly 220 preferably by activation of release button 242. This allows instruments associated with instrument mount assembly 15 220 to be quickly and conveniently removed and replaced or exchanged.

In a preferred embodiment, first and second prongs 262 and 263 of tie pin 240 have first and second projections 267 and 268 which releasably attach tie pin 240 to shaft grip 226. Grip housing 274 of shaft grip 226 is covered with a sleeve having a deep counterbore 278 and small through hole 279. The depth of counterbore 278 is longer than 20 the exterior of grip housing 274 so as to form internal space 290 (see Figure 25) when assembled. First and second prongs 262 and 263 can be flexed to position projections 267 and 268 relatively close together for insertion through hole 279 where projections 267 and 268 can then expand apart locking projections 267 and 268 behind surface 280.

Preferably, projections 267 and 268 have lead-ins 291 and 292 which urged projections 267 and 268 together as they are advanced through hole 279 so that shaft grip 226 can simply be aligned with lead-ins 292 and 292 and then snapped into place without any further action. Alignment of hole 279 is generally quite simply accomplished as the cylindrical exterior surface 277 of sleeve 260 is slidably received in a substantially coaxial arrangement within center bore 219 of clutch member 225. Clutch member 225 may optionally have first and second flexures 281 and 282 having first and second retaining features 283 and 284 so that it may be snapped in place and thereafter retained within mount body 222.

As mentioned above, shaft grip 226 may be released from tie pin 240. To separate tie pin 240, it is necessary to flex first and second prongs 262 and 263 together so that projections 267 and 268 will again be positioned to fit through hole 280. This may be accomplished by providing a raised portion 264 having a ramp 266 on tie pin 240. A sliding member may be advanced up tie pin 240 and over ramp 266 and raised portion 264 thus flexing prongs 262 and 263 inwards. Preferably, the sliding member is a tip portion 289 of release button 242. Tie pin 240 is slidably received within blind hole 272 of release button 242. The internal diameter of blind hole 272 is small enough so that when it is advanced over ramp 266 and/or raised portion 264, prongs 262 and 263 are flexed inwards. Preferably, the entrance to blind hole 272 has an internal chamfer 288 so that ramp 266 is smoothly engaged as release button 242 is advanced.

Release button 242 preferably has a generally cylindrical body 285 which is slidably received within mating bore 294 (see Figure 25) of mount body 222. Release button 242 is retained in place, and its sliding travel limited, by release button flange 241

on one end and spring clip or e-clip 293 assembled within e-clip groove 286 on the other end. Spring material 246, such as a wave spring washer or foam material, may be disposed between release button flange 241 and mount body 222 to bias release button 242 outwards. Transverse to blind hole 272 tip portion 289 also has a clearance slot 287
5 through which base post 230 passes.

For clarity only, Figures 22A-25 have illustrated instrument mount assembly 220 without hinge member 115 and cam 145 attached. However, hinge member 115 having rail grip 116 is preferably pivotally mounted, with cam 145 in place, by way of pins or the like at hinge mount 228 as described above with reference to instrument mount
10 assembly 20. As discussed above, cam 145 may be rotated about cam guide 223 using base lever 122 to secure the instrument mount to a rail or other suitable structure.

The retractor and instrument mounts described above can be used to mount and stabilize a great number of instruments for use during surgery. Preferably, the retractor and instrument mounts are used to mount a mechanical stabilizer for stabilizing at least a
15 portion of the beating heart during CABG surgery or the like. Described below are a number of mechanical stabilizer embodiments that are particularly beneficial for stabilizing the beating heart, especially when used in conjunction with the retractors and instrument mounts described above.

Tissue Stabilizers

20 Once access to the heart is achieved, and the heart is positioned if necessary, a means for stabilizing the beating heart is introduced through the opening created and at least one component of the stabilizing device of the invention is brought into contact with the beating heart. The surgeon then applies a stabilizing force to the beating heart via the

stabilizing means which may then be fixed in place by attachment to a fixed support.

When a retractor or platform is fixed in an open position to expose the heart, the retractor platform may also provide the stable support structure to which the stabilizing means is affixed. When the position of the stabilizing means is fixed by attachment to a stable
5 support or to the retractor platform, the stabilizing force is maintained for the duration of the procedure.

The structure of the portion of the stabilizing means which contacts the heart may include one or more contact members which exert a stabilizing force on the heart proximate to the site of the anastomosis. A pair of contact members may be plates or
10 rectangular members which are placed on either side of the target coronary artery at the site of the anastomosis and which may have friction means or tissue spreading or compressing apparatus associated therewith. The contact members may also be provided by a platform which may be substantially planar or which may be contoured to fit conformingly on the surface of the heart. The stabilizing means may also include a shaft
15 means having several alternative embodiments to facilitate adjusting the position and orientation of the instrument. For example, the shaft means may have an adjustable length and the axis of the shaft means may have at least one ball joint disposed within its length such that the orientation of the shaft means relative to another structure such as the contact members or stable support may be continuously varied. As is apparent from the
20 description of the several embodiments, each of the individual embodiments described and illustrated herein has discrete components and features which may be readily separated from or combined with the features of any of the other several embodiments.

Referring to Figures 33-37, a preferred stabilizer assembly for stabilizing the beating heart is comprised of a foot or base portion 553 attached to a rigid or semi-rigid shaft means or connecting shaft 3. Base portion 553 typically has one or more contact members 1 adapted to contact the heart adjacent the site desired to be stabilized. The contact members 1 may be substantially planar, may be slightly curved to conform to the shape of the heart, or may be a non-conforming curve to establish contact between only a portion of the contact member 1 and the beating heart. The shape of the contact members may be varied depending on the clinical assessment by the surgeon, the design of the other features of the stabilizing means, or the design of other instruments used to complete the anastomosis. In some embodiments the contact members 1 may have apertures, openings or attachments to facilitate connection with sutures or other devices to achieve the requisite stabilization, occlusion of the target vessel, or exposure of the target vessel. Examples of suitable base portions and contact members can be found, for example, in co-pending U.S. Patent Application Serial Number 08/931,158 filed on September 16, 1997, entitled "SURGICAL INSTRUMENTS AND PROCEDURES FOR STABILIZING THE BEATING HEART DURING CORONARY ARTERY BYPASS GRAFT SURGERY", the entirety of which is herein incorporated by reference.

Referring to Figures 33 and 34, the proximal end of connecting shaft 3 has handle mechanism 468 assembled thereto which, among other things, provides the user with a means for locking an end effector operably attached to the distal end of connecting shaft 3. The mechanism 468 is rotatably secured to the proximal end of the shaft means 3 and is formed at a selected angle to the shaft means to permit a surgeon to swivel the mechanism to a preferred position where the knob 504 is more readily accessible to allow

quickly locking the shaft means 3 in the orientation selected. In addition, the angled axis of the knob 504 relative to the shaft means 3 reduces the tendency of the shaft means 3 to rotate about its axis when a surgeon applies torque to the knob 504 to lock the associated locking mechanism. The knob 504 is secured to a screw 539 by suitable means such as
5 press fitting, bonding, etc. Right and left handle covers 540,541 comprise the handle 503 and provide the support for the handle mechanism. When assembled, the covers define generally a cylinder formed with a selected curvature. A secondary inner molding, generally indicated at 542, includes various integrally formed annular walls and shoulders for supporting and containing the knob 504 and screw 539, as well as a cooperating nut
10 543, and arcuate wedge 544, a shaft retaining ring 545, the proximal end of the shaft means 3, and a proximal end of the translatable pushrod 505. The proximal end of the shaft means 3 includes an annular retaining ring slot 546 which secures the proximal end of the shaft means 3 within suitable annular walls in the corresponding end of the handle covers 540, 541 when the retaining ring 545, confined by shoulders in the inner molding
15 542, is snapped into the slot 546 and the covers are assembled. The nut 543 is confined by shoulders in the inner molding 542, and the arcuate wedge 544 is slidably confined by correspondingly arcuate walls 547 also formed in the inner molding.

As may be seen, rotation of the threaded screw 539 within the confined threaded nut 543, causes translation of the screw, pivoting and thus translation of the translatable
20 wedge 544 which abuts the screw, and translation of the pushrod 505 which abuts the translatable wedge. As is further described relative to Figures 35-37, any tightening or loosening of the screw 539, however slight, will cause a corresponding translation of the pushrod 505 into or out of the shaft means 3.

As depicted in the Figures, the shaft means 3 and thus the pushrod 505, are formed with a slight arcuate configuration, which permits additional degrees of freedom and movement and orientation of the distal end of the shaft means 3 and thus of the heart contact member 1. Rotation of the shaft means 3 about the axis of confinement within the shaft grip 495 or 495a, moves the distal end of the shaft means 3 through a circular path while changing the angles through which the contact member 1 can be oriented. This allows a surgeon to conveniently achieve a wider range of positions and orientations of the contact member relative to the patient's heart, while keeping the proximal end of the shaft means 3 and handle mechanism 468 out of the way as much as possible.

Figures 35-37 illustrate an associated mechanism for maneuverably supporting the various embodiments of the contact member 1 and for cooperatively assisting in the quick locking of the contact member by a partial rotation of the knob 504 once the member is positioned. To this end, the distal end of the shaft means 3 is provided with exterior threads matching interior threads in a ball/socket 548. The distal end of ball/socket 548 is provided with slots 549, whereby the remaining material comprises short extended tips 550 which, when bent in or inwardly formed, form a socket. A ball/post 551 includes a ball at one end and a post at the other. When the mechanism is assembled, the ball/post 551 is inserted into place within the ball/socket 548 with the ball in the socket and the post protruding from the ball socket. A mechanism for providing a preloaded source, such as a compression spring 552, is coupled to the ball/socket 548 abutting the ball. The spring 552 is urged by the distal end of the shaft means 3 to exert a preloaded or constant minimum force against the ball of the ball/post 551. The post of the ball/post 551 is solidly fixed as by pressing fitting, welding, etc., to the contact member 1. The distal end

of the pushrod 505 passes through the spring 552 to abut the ball of the ball/post 551.

Thus when the screw 539 is not tightened, the distal end of the pushrod 505 exerts a slight pressure against the ball, however the spring 552 maintains a preloaded force

against the ball sufficient to maintain the contact member 1 at any orientation set by a

5 surgeon. When the screw 539 is tightened, the pushrod 505 is forced against the ball to

prevent any further movement of the contact member 1. As may be seen, the contact

member 1 can be tilted to assume many orientations since the narrow center of the post

can tilt into any of the four slots 549 in the ball/socket 548. In addition, simultaneous

rotation of the curved shaft means 3 provides a surgeon with an even greater variety of

10 orientations of the contact member relative to a patient's heart.

The contact member 1 includes a preferred configuration which improves the size

of the area of the heart which is visible to a surgeon while still providing the required

suppression of heart movement necessary to enable the efficient construction of the

anastomosis. More particularly, the pair of spaced-apart contact members 1 extend from

15 a common base portion 553, which uniquely first extends back away from the tips of the

contact members at the point of attachment to the post, as shown at reference number

554. The spaced contact members 1 then curve downward away from the common base

portion 553 and back past the post and away from the shaft means 3. As may be seen in

the Figures 35-37, the contact member 1 of this embodiment uniquely is attached to the

20 post on the same surface as the surface that bears against the surface of the beating heart.

Since the members 1 separate at the base portion 553 at a point 555 behind the distal end

of the shaft means 3, a surgeon has an unobstructed and thus optimum view of the heart

even below the distal end of the shaft means 3.

The contact members preferably include friction means 556 selectively secured to the bottom surfaces thereof to more securely engage a beating heart. In addition, the tips of the contact members are bent upward in the form of "ski tips" to lessen their impact when the contact members are firmly pressed against a beating heart to suppress the anastomotic site.

Although screw means 539/504/543 is illustrated herein as a locking mechanism of the handle mechanism 468, it is to be understood that other mechanisms may be employed. For example, a cam/lever mechanism may be attached to a rod which in turn imparts a pivoting movement or translation to a suitable bellcrank or pivotable member, which in turn imparts translation to pushrod 505 of the shaft means 3. Thus, locking mechanisms other than those specifically described herein may be used.

The basic configuration as just described with reference to base portion 553 provides the maneuverability necessary to access and stabilize any desired vessel on the surface of the beating heart. However, the exact manner and position in which the stabilizer may be placed relative to the vessel and the surgical techniques preferred by an individual surgeon may vary significantly. Accordingly, there is some potential that certain combinations of stabilizer positioning may interfere somewhat with the preferred surgical technique of a particular surgeon. The embodiments illustrated below with respect to Figures 38-40B alleviate any such problems.

One useful variation, as illustrated in Figure 38, connects connecting shaft 3 to the base portion of the stabilizer at a position which is generally offset from the center or off-center. Base portion 710 is again typically formed of a unitary piece of sheet material and has a curved back portion in which connecting shaft 3 is attached to an extension of

the same surface which carries the contacting members, except that the connecting point 718, to which ball/post 551 is attached is positioned away from the center and therefore away from the space between contact members 712 where the anastomosis would be performed. This configuration tends to ensure that connecting shaft 3 will not interfere
5 with the surgical access to the center area of the base portion. Of course, the connection can be offset from the central region in either direction.

In addition, base portion 710 illustrates a number of features for improving the traction and vessel presentation during a CABG procedure on a beating heart. Contact members 712 of base member 710 have portions 713 having an increased width and
10 which are preferably substantially flat or slightly curved to conform to the heart. This configuration provides a larger area for coined regions 715, which represent indentations on the bottom surface for receiving a traction material, thus providing greater traction against the surface of the heart.

Further, base portion 710 provides a smaller open space between contact members
15 712. In a preferred embodiment, the spacing 716 between contact members 712 is less than about 0.350 inches, more preferably less than about 0.300 inches, and most preferably about 0.25 inches. This minimized spacing provides stabilization closer to the vessel and, in some instances, the compressive forces applied through contact members 712 actually tend to present the vessel upwards between contact members 712 in a more
20 favorably pronounced manner. The tip portions 714 of contact members 712 are angled upwards from the surface of the heart to minimize any possible trauma to the heart during use.

As just discussed, the base portions (550 or 710) can be manipulated or oriented relative to the end of the connecting shaft 3 by virtue of the ball and socket joint between base portion 553 and connecting shaft 3. The amount of angular manipulation or travel available is somewhat limited as ball/post 551 eventually bottoms out or stops against either the bottom of slots 549 or extended tips 550. Thus, the contact members have a limited range of movement relative to connecting shaft 3 based upon the nominal mounting relationship between the contact members and the ball/post. Accordingly, for some procedures, it may be desirable to have a different nominal relationship between the contact members and the ball/post to shaft connection.

Referring to Figures 39-40B, base member 720 illustrates an alternative orientation of ball/post 551. Instead of being angled away from the contact members, base member 720 has a back portion 721 which allows ball/socket 551 to be mounted generally parallel to contact members 722. Ball/post 551 preferably extend towards contact members 722 as shown, but may also extend the opposite direction away from the contact members. The connecting point 723 is preferably offset a distance 724 from the central area between the contact members 722. The connecting point 723 is also off set a greater distance 726 from the contacting place of contact members 722. In nominal position of base portion 722 relative to ball/post 551, this configuration tends to keep the connecting shaft 3 clear from the central portion between contact members 722.

Furthermore, relative to connecting shaft 3, contact members 722 can be maneuvered through a range of motion different from base member 553 due to the initial orientation of ball/post 551.

Because the preferred location of the attachment of the connecting shaft 3 to the base portion may be different from surgeon to surgeon and from procedure to procedure, it may be desirable to have the ball/post moveable to more than one location. In one embodiment shown in Figure 41, for example, ball/post 562 has threaded end 561 which may be threaded into any desired threaded receiving hole 563 provided in stabilizer base 560. Ball post 564 is preferably provided with one or more flats 564 on the exterior thereof to facilitate tightening or loosening of the threaded connection. In the embodiment shown, stabilizer base 560 has threaded receiving holes 563 to provide center, offset right, and offset left connecting positions.

Referring to Figures 42 and 43, ball/post 572 may be captured within slot 571 formed in stabilizer base 570. Slot 571 preferably has two or more positions where the ball/post can be positively locked. In a preferred embodiment, slot 571 preferably has two or more key-hole openings 573. Key openings 573 are sized to receive first post portion 577 having an outside diameter which closely matches the inside dimension of key opening 573. First post portion 577 of ball/post 572 is released from key hole 573 by pulling ball post in the direction indicated by arrow 579 until second post portion 578 is positioned within keyhole 573. Second post portion 578 is sized to have an outside diameter small enough to fit and traverse through slot 571. Ball/post 572 may then be traversed along the path defined by slot 571 until the next desired key hole is reached, which may then be engaged by first post portion 577 to secure ball/post 572 in position on stabilizer base 570.

First post portion 577 may be kept in engagement with keyholes 573 by any convenient manner. For example, ball/post 572 may be spring biased in the locked

position between upper flange 574 and lower flange 575, preferably using spring washers 576 as shown. Ball/post 572 may also be locked into operating position within keyholes 573 by using a retaining or locking clip, such as locking clip 580 illustrated with reference to Figures 44 and 45. Locking clip 580 has slot 584 adapted to slide over
5 second post portion 578. Locking clip 580 includes a thin portion 585, a thick portion 583, a transition ramp 582 between thin portion 585 and thick portion 583, and a grip or handle portion 581. With locking clip 580 in the open position shown in figure 44, ball post 572 is free to move upwards in the direction of arrow 579, thus releasing first post portion 577 from key hole 573. When locking clip 580 is moved in the direction
10 indicated by arrow 586, the outer thickness of thick portion 583 is wedged between lower flange 575 and stabilizer base 570, thus locking ball/post 572 in place within keyhole 573.

Stabilizer base 590 in Figure 46 has ball/post 592 mounted to an articulating member which is moveable between two or more positions. Preferably, ball/post 592 is
15 mounted on first end 594 of pivoting link 591 which is pivotably attached to stabilizer base 590 at pivot pin 596. Preferably, pivot pin 596 is centrally located on pivoting link 591. At second end 593 of pivoting link 591, a locking knob 595 may be provided to engage stabilizer base 590. Preferably, locking knob 595 has a threaded shaft or other such fastening or locking feature which engages mating threaded holes (typically one
20 positioned under locking knob 595 and one under ball/post 592) in stabilizer base 590. The ball/post 592 and locking knob 595 are preferably spaced equal distances from pivot pin 596 such that when pivoting link 591 is rotated as indicated by arrow 597, the position of ball/post 592 and locking knob 595 are reversed.

Another embodiment of a tissue stabilizer having an adjustable attachment position of the connecting shaft is illustrated in Figures 47-50. Stabilizer base assembly 625 includes top member 605 and stabilizer base 600, having contact members 606 and 607 and notch or relief 603 under which a vessel may safely pass without being occluded.

5 At least a portion of stabilizer base 600 has outer profile 601 which is generally curved or circular at a predetermined radius. Top member 605 has a mating interior curvature such that stabilizer base 600 and top member 605 concentrically rotate relative to each other, preferably about a common center point. Ball/post 602 may be attached at a convenient position, typically centered, on top member 605. Rotation of top member 605 relative to
10 stabilizer base 600, as indicated by arrows 620 and 619, thus adjusts the position of ball/post 602 along an arcuate path relative to contact members 606 and 607.

To facilitate the secure attachment and smooth rotation of top member 605 relative to stabilizer base 600, top member 605 may be provided with one or more projections adapted to be received within guide slots provided in stabilizer base 600. In a
15 preferred embodiment, top member 605 has side projections or rails 608 and 609 which snap into lower slots or channels 611 and 610 in stabilizer base 600 as top member 605 is urged into a concentric position over stabilizer base 600. Rails 608 and 609 slide within channel 611 and 610 to maintain a secure attachment and controlled rotation of top member 605 and stabilizer base 600. Top member 605 may optionally have tab 612
20 adapted to be received within upper slot 604 on stabilizer base 600. Upper slot 604 may have a plurality of detents or teeth which form a desired number of detented positions as tab 612 is rotated around the path of upper slot 604. In a preferred embodiment, detented position 617 is formed between tooth 613 and slot end 616 and detented position 618 is

formed between tooth 614 and tooth 615. Of course, detented positions may be created at any desired location using a variety of alternate constructions. Preferably, the detent action of tab 612 allows the operator to manually select a position of ball/post 602, but then holds the position of top member 605 relative to stabilizer base 600 against
5 movement during use to ensure effective stabilization of a target vessel on the beating heart.

In addition to the critical function of stabilizing the beating heart, it is also important for the tissue stabilizer to present the stabilized coronary artery in a manner which allows sutures to be easily placed around the mouth of the arteriotomy as required
10 to create the anastomosis. Figures 51A-54 illustrate a tissue stabilizer embodiment involving a base portion having a single contacting surface for stabilizing a target vessel on the beating heart and a mechanical bail element to facilitate optimal vessel presentation.

Referring to Figures 51A and 51B stabilizer base 740 is shown attached to
15 connecting shaft 3 using ball/post 730. Connecting shaft 3 is shown connected generally to the center of stabilizer base 740 at approximately a right angle, however, as discussed above, the ball/post 730 could be connected at any desired offset or orientation or the position of ball/post 730 could be adjustable. Stabilizer base 740 preferably has a single contacting surface 742 which may be flat or curved to at least partially conform to the
20 surface of the heart. Contacting surface 742 is sized to provide sufficient contacting area such that sufficient compressive force can be applied to the beating heart to achieve effective immobilization or stabilization of a target coronary artery.

Stablizer base 740 preferably has an extending frame member or bail 745 attached thereto. Bail 745 may be a thin, round or square cross-sectioned member, and is preferably a stainless steel wire. Bail 740 has a bail portion 756 which is generally parallel to stabilizer base 740 and may have relieved sections 747 formed therein so as not to occlude the vessel during use. Bail portion 756 may have tissue gripping features, such as teeth 755. In an optional embodiment, bail portion 756 may be provided with rotating cover or a spiral wound thread (not shown) so that bail portion may be more easily repositioned, under a stabilizing load, over the surface of the heart as discussed below.

In a preferred embodiment, bail 745 is moveable relative to stabilizer base 740. Bail 745 can be moved in or out in the direction indicated by arrow 750 to cause bail section 756, which is generally parallel with stabilizer base 740, to compress tissue towards stabilizer base 740 or stretch tissue away from stabilizer base 740. Thus, bail 745 can be moved in and out to compress or stretch the tissue surrounding a coronary artery until the optimum presentation for performing the anastomosis is achieved. The generally parallel portion may be vertically offset from contacting surface 742 by a distance 757 which is typically about 0.050 inches to about 0.200 inches.

Although bail 745 may be attached in a number of ways, bail 745 is preferably formed with first and second end portions 748 and 749 having detents or teeth 746.

Stabilizer base 740 preferably has channels 751 and 752 for receiving end portions 749 and 748 respectively. Channels 751 and 752 preferably have internal mating teeth 753 for engaging teeth 746. End portions 748 and 749 can be incrementally advanced into channels 752 and 751 as teeth 746 deflect and release from a mated position relative to

teeth 753 and then successively engage the next mated position. Stabilizer base 740 may include cover 754 over channels 751 and 752. So that the stabilizer can be removed from around a completed anastomosis, at least one end of bail 745 is detachable from stabilizer base 740. In a preferred embodiment, stabilizer base 740 is substantially symmetrical
5 allowing bail 745 to be assembled from either side in a right or left handed configuration.

Bail 745 is preferably flexible or semi-flexible relative to stabilizer base 740. As a result of its inherent flexibility, bail 745 applies a predetermined force against the heart that, under operating conditions, may be generally independent of the stabilizing force applied to stabilizer base 740 to stabilize the beating heart. That is, once stabilizer base
10 740 is forced against the surface of the heart, the force applied by bail 745 is a function of its mechanical spring rate relative to stabilizer base 740.

Figures 52A and 52B illustrate another single contact stabilizer base having a bail 762 which is secured at only one end. Stabilizer base 760 may have a housing 765 having a series of internal teeth (not shown). Bail 762 has a toothed end 766 which is
15 received within housing 765 to engage with the mating teeth provided therein. As with the embodiment above, bail 762 has a generally parallel portion 763 which is moveable relative to stabilizer base 760 in the direction generally indicated by arrow 767 to stretch or compress the surrounding tissue for optimum vessel presentation. Bail 762 may have tab 761 to facilitate grasping by an instrument, such as for example forceps 761. The free
20 end 764 of bail 762 is preferably rounded or somewhat bulbous so as to be atraumatic. Because bail 762 attaches only at one end, the stabilizer can be easily removed from the completed anastomosis without removing bail 762 from stabilizer base 760.

In another embodiment of the stabilizer, the wire frame member or bail may have a drive mechanism for moving the bail relative to the stabilizer base. Referring to Figure 53 stabilizer base 770 has housing 771 which is constructed with guide channel 774 having gear 775 mounted for rotation therein. Bail 772 has a toothed end 773 which may be assembled within guide channel 774 such that rotation of gear 775 causes bail 772 to be moved in and out in the direction indicated by arrow 43. Gear 775 may be driven by any suitable tool, for example, gear 775 may have a drive hole 778 for engagement by a suitable drive tool 771.

Another driven bail stabilizer is shown in Figure 54. In this embodiment, stabilizer base 780 has threaded shaft 781 preferably supported at its end portions by bushings or bearings 783 and 784. One end of the threaded shaft is connected to a flexible drive 785 through a flexible or universal joint 791. The flexible drive may be routed up connecting shaft 3. Preferably flexible drive 785 is secured to connecting shaft 3 by way of a thin polymeric coating. Bail 782 is connected to threaded collar 787 which cooperates with threaded shaft 781 to move bail in and out relative to stabilizer base 780 in the general direction indicated by arrow 790. The screw and collar drive mechanism is preferably concealed by housing 788 which has only a small slotted opening 786 allowing passage of bail 782.

With each of the flexible bail embodiments described above, stabilization and vessel presentation are relatively independent. First, the beating heart is typically stabilized using a compressive force delivered by way of the single contacting surface provided by the stabilizer base. The bail may then be manipulated in or out to obtain the optimum presentation of the vessel for whatever surgical procedure is underway. For

example, one bail position may be optimal for creating the arteriotomy, another bail position for insertion of a shunt or like device (should one be used), another bail position for creating the anastomosis, and so on. All the while, the stabilization of the beating heart itself remains optimized by the contacting surface of the stabilizer base.

5 The Stabilization System

Preferred embodiments for each of the retractor, the instrument mount and the tissue stabilizers have been discussed in detail above. While each component may be utilized separately, superior access and stabilization can be achieved when the multiple components are used together for performing a minimally invasive cardiac surgery, preferably through a sternotomy approach. Referring to Figure 55, retractor assembly 10 900, including drive mechanism 910 and first and second platform blades 915 and 920, may be used to spread the sternum, providing access and direct visualization to the thoracic cavity. Retractor assembly 900 also allows sutures to be fixed or organized. Stabilizer assembly 800 isolates and provides local immobilization of the target vessel on 15 the beating heart. Instrument mount assembly 850 facilitates precise maneuvering of the stabilizer and ensures a stable, motion free mount at the desired position and orientation.

To begin a typical beating heart CABG procedure using the preferred stabilization system illustrated in Figure 55, drive mechanism 910 is preferably placed in the fully closed position with moveable housing 925 positioned against or adjacent fixed housing 20 930. First platform blade 915 is then assembled to moveable housing 925 and a second platform blade 920 is assembled to fixed housing 930. After ensuring that platform blades 915 and 920 are fully and securely attached to drive mechanism 910, engaging members 935 of platform blades 915 and 920 are securely seated on the incised sternum

created using standard surgical procedures. Drive handle 940 may then be rotated clockwise to separate platform blades 915 and 920, thus creating the desired opening for accessing the beating heart.

If positioning the heart using sutures to position the heart, the sutures may be placed through the tissue at the desired location and secured to platform blades 915 and 920.. Sutures 945 may be slid into suture holder slots 950 to engage the suture. To ensure proper a proper hold, only one suture strand is preferably engaged within each suture holder slot 950. Sutures 945 are released from platform blades 915 and 920 by concurrently pulling back and up on suture 945 while pulling the suture through the suture holder slot 950.

With the heart positioned as desired, instrument mount assembly 850 may be assembled to platform blade 920 (or 915) by hooking stabilizer mount base 955 onto rail 960 (or 961) at the desired location and moving the base lever (not visible in this view) clockwise to the closed position to secure instrument mount assembly 850 onto rail 960. Mount body 110 may be oriented to the desired angle by way of ball joint 965 and locked into place by turning the top mount knob 855 clockwise.

Stabilizer base 810, having contact members 812 and 814, may then be positioned on the epicardium of the beating heart by gently lowering connecting shaft 820 using one hand to guide stabilizer base 810 onto the target area on the heart. Incremental pressure is applied to stabilizer base 810 situated on the epicardium until the desired immobilization or stabilization is achieved. Connecting shaft 820 is secured in the desired position by turning side mount knob 860 clockwise and stabilizer base 810 is secured in the desired position relative to connecting shaft 820 by turning the stabilizer shaft knob 830

clockwise. With the beating heart stabilized the anastomosis, or other desired procedure, is completed.

To remove stabilizer base 810, connecting shaft 820 is held with one hand while side mount knob 860 is loosened with the other hand. Stabilizer base 810 is then carefully removed from the anastomotic site. The base lever is moved to the open position to release instrument mount assembly 850, and stabilizer assembly 800 mounted thereto, from rail 960 on platform blade 920. When the entire bypass procedure is completed, drive handle 940 is rotated in the counter clockwise direction to close drive mechanism 910 and platform blades 915 and 920. Retractor assembly 900 may then be gently removed from the access incision. To remove platform blades 915 and 920 from moveable housing 925 and fixed housing 930, respectively, release latches 970 are manually activated and platform blades 915 and 920 may be pulled generally straight away from drive mechanism 910. Drive mechanism 910 may then be sterilized and prepared for use in a subsequent procedure.

While certain embodiments are illustrated in the drawings and have just been described herein, it will be apparent to those skilled in the art that many modifications can be made to the embodiments without departing from the inventive concepts described. For purposes of illustration only, the principles of the present invention has been generally described with reference to a coronary artery bypass procedure, but may readily be applied to other types surgical procedures not specifically described. Many other uses are well-known in the art, and the concepts described herein are equally applicable to those other uses. Further, the different components of the various exemplar

embodiments described above can be combined in any desirable construction.

Accordingly, the invention is not to be restricted except by the claims which follow.
